Abstract

The Mars Organic Molecule Analyzer (MOMA) and Sample Analysis at Mars (SAM) instruments onboard the Exomars 2022 and Mars Science Laboratory rovers, respectively, are capable of organic matter detection and differentiating potentially biogenic from abiotic organics in martian samples. To identify organics, both these instruments utilize pyrolysis–gas chromatography coupled to mass spectrometry, and the thermochemolysis agent tetramethylammonium hydroxide (TMAH) is also used to increase organic volatility. However, the reactivity and efficiency of TMAH thermochemolysis are affected by the presence of calcium perchlorate on the martian surface. In this study, we determined the products of TMAH pyrolysis in the presence and absence of calcium perchlorate at different heating rates (flash pyrolysis and SAM-like ramp pyrolysis with a $35^{\circ}\text{C}\cdot\text{min}^{-1}$ heating rate). The decomposition mechanism of TMAH pyrolysis in the presence of calcium perchlorate was studied by using stepped pyrolysis. Moreover, the effect of calcium perchlorate (at Mars-relevant concentrations) on the recovery rate of fatty acids with TMAH thermochemolysis was studied. Results demonstrate that flash pyrolysis yields more diversity and greater abundances of TMAH thermochemolysis products than does the SAM-like ramp pyrolysis method. There is no obvious effect of calcium perchlorate on TMAH degradation when the $[\text{ClO}_4^-]$ is lower than 10 weight percent (wt %). Most importantly, the presence of calcium perchlorate does not significantly impact the recovery rate of fatty acids with TMAH thermochemolysis under laboratory conditions, which is promising for the detection of fatty acids via TMAH thermochemolysis with the SAM and MOMA instruments on Mars. Key Words: Calcium perchlorate—TMAH thermochemolysis—Pyrolysis-GC-MS—Mars—SAM and MOMA. Astrobiology 21, xxx–xxx.

1. Introduction

NASA's 2008 PHOENIX Mars lander and its wet chemistry laboratory (WCL) was the first experiment on Mars, which detected $\sim 0.4\text{--}0.6$ weight percent (wt %) ClO_4^- ions

in the martian soil (Hecht *et al.*, 2009). After this initial *in situ* detection, calcium and magnesium perchlorates were identified at the landing site (Hecht *et al.*, 2009), and Kounaves *et al.* (2014b) concluded that the soil samples analyzed by the Phoenix's WCL could be composed of an $\sim 3:2$ ratio of

Ca(ClO₄)₂ to Mg(ClO₄)₂ phases. Later, chlorine-bearing compounds were detected by the Sample Analysis at Mars (SAM) instrument, 1 of 10 instruments on the Mars Science Laboratory Curiosity rover, such as hydrogen chloride (HCl) gas, chloromethane, dichloromethane, chlorobenzene (Ming *et al.*, 2014), and isomers of dichlorobenzene (Millan *et al.*, 2019). These chlorine-bearing hydrocarbons have been attributed to the reaction of oxychlorine-related species with organic compounds during the pyrolysis of the samples analyzed with SAM (Freissinet *et al.*, 2015; Millan *et al.*, 2019). From these results, a reinterpretation of the data obtained with the gas chromatography–mass spectrometry (GC-MS) experiment onboard the 1976 Viking landers suggests that perchlorates and/or chlorates were also present in the samples analyzed by these experiments (Sutter *et al.*, 2017a; Guzman *et al.*, 2018). Furthermore, analysis of the Rocknest wind ripple with the SAM instrument and a comparison with results obtained from laboratory measurements indicate that calcium perchlorate is a better candidate for the perchlorate species than Fe, Mg, Na and K perchlorates (Leshin *et al.*, 2013). More recently, chloride-bearing hydrocarbons have been produced by the reaction of oxychlorine-related species with organics in SAMs pyrolysis oven. This led to the conclusion that in modern sand deposits and some much older rocks, Ca and Mg perchlorates are the most likely sources of chlorine-related products (Freissinet *et al.*, 2015; Millan *et al.*, 2019).

The detection of widespread perchlorates and likely chlorates on Mars led to several studies related to the potential effect of perchlorates on the detection of organic compounds with various instruments. Perchlorate is a strong oxidizing agent because oxygen can be released from the decomposition of perchlorates and could be the main cause of the degradation of organic compounds. The thermal decomposition of perchlorates, including lithium, sodium, potassium, magnesium, iron, aluminum, and calcium perchlorates, has been analyzed by using a thermobalance from previous experiments (Marvin and Woolaver, 1945). Two possible mechanisms for the thermal decomposition of a perchlorate were proposed (Marvin and Woolaver, 1945): (1) by gradual hydrolysis of hydrated compounds to yield perchloric acid and an oxide, such as magnesium, iron, and aluminum perchlorates, and (2) by dehydration followed by decomposition to yield oxygen and chloride, as in the case of lithium (~440°C), sodium (~480°C), potassium (~540°C), and calcium (~405°C) perchlorates. The salts may be dehydrated first and then decomposed when the temperature is high enough to force their release.

The temperature of oxygen release from perchlorate can be affected by other minerals present in a solid sample. For example, the decomposition temperature of calcium perchlorate or another oxychlorine species can decrease due to the presence of iron phases (Bruck *et al.*, 2014; Hogancamp *et al.*, 2018). Regardless of the perchlorate phase, oxygen will be released from any perchlorate in solid samples on Mars when the SAM instrument ovens are heated, leading to the oxidation of organic compounds into carbon dioxide. The main consequence of this is that organic matter is degraded and would not be detected (Ming *et al.*, 2014). Furthermore, the abundance of oxychlorides varies by one order of magnitude (Farley *et al.*, 2016). Some experiments have shown that there should be a minimum ratio of 4.7:1

between organic matter and perchlorate to ensure the detection of organic molecules with pyrolysis–gas chromatography coupled to mass spectrometry (Pyr-GC-MS) (Kounaves *et al.*, 2014a) without major impact from the perchlorate. In addition, HCl produced during the thermal decomposition of martian perchlorate can react with soil carbonates leading to low temperature inorganic CO₂ release, and the presence of calcium chloride (CaCl₂), which is formed from the reaction between calcite and HCl, has been confirmed by X-ray diffraction experiments (Cannon *et al.*, 2012). Therefore, the detection of organic fragments, not CO₂ alone, should be used as definitive evidence for organics in martian soils (Cannon *et al.*, 2012).

Perchlorate not only affects the type and the number of organic compounds detected (Steininger *et al.*, 2012), it can also react with organic compounds to form chlorine-related compounds. For example, Guzman *et al.* (2018) observed the presence of chlorobenzene at a concentration of 0.08–1.0 ppb (relative to sample mass) in Viking Lander 2 (VL-2) data at a pyrolysis temperature between 350°C and 500°C. They concluded that the reaction of indigenous organic carbon and instrument contamination with martian perchlorate during the pyrolysis process is the likely source of the chlorobenzene. Laboratory experiments confirm that perchlorates mixed with organic molecules with different molecular weights (low, medium, or high) will form chloride-related gases such as HCl, carbonyl dichloride (CCl₂O), and carbon tetrachloride (CCl₄) (Sephton *et al.*, 2014). However, Montgomery *et al.* (2019) reported that the presence of perchlorate and other oxyanion salts inhibited the detection of organic compounds when analyzed by Pyr-GC-MS; removing perchlorates and sulfates of Atacama Desert showed identifiable biomarkers associated with cyanobacteria.

Both the Mars Organic Molecule Analyzer (MOMA) instrument onboard the ESA/Roscosmos ExoMars rover and the SAM instrument on the NASA Curiosity rover can detect organic molecules. MOMA and SAM are analytical suites that utilize Pyr-GC-MS. MOMA carries three derivatization/thermochemolysis agents (Goesmann *et al.*, 2017), that is, N-tert-butyltrimethylsilyl-N-methyltrifluoroacetamide/N,N-dimethylformamide (MTBSTFA/DMF, for carboxylic and amino acids, nucleobases, amines, and alcohols), DMF dimethyl acetal (for amino acids, fatty acids, and primary amines with chiral centers), and tetramethylammonium hydroxide (TMAH) in methanol (for lipids and fatty acids, when driven to higher temperatures). SAM carries only MTBSTFA/DMF and TMAH in methanol (Mahaffy *et al.*, 2012). These derivatization/thermochemolysis agents increase the volatility of organic molecules with labile groups, such as amino acids, carboxylic acids, and nucleobases (He *et al.*, 2019a, 2020). TMAH is very useful for the liberation of polar molecules from macromolecules and the volatilization of fatty acids, but the decomposition of TMAH at elevated temperatures above 500°C (Morisson *et al.*, 2017) can cause additional issues that complicate organics detection. The degradation of TMAH at relatively low temperatures (lower than 200°C) has been studied, and different TMAH degradation mechanisms have been reported (Musker, 1967; Chempath *et al.*, 2008, 2010; Long and Pivovar, 2012), but no study has reported on the by-products of TMAH pyrolysis at elevated temperatures.

The thermal degradation of TMAH can proceed via two different pathways. The first pathway is a nucleophilic substitution reaction mechanism (the bimolecular or S_N2 pathway) defined by the synchronous formation of one bond as another bond is broken. In this case, it is the nucleophilic attack by OH^- on the CH_3 group that produces trimethylamine (TMA) and dimethyl ether (Musker, 1967). The second pathway is the ylide one wherein the decomposition of TMAH to give TMA and dimethyl ether results from the initial removal of a proton from the quaternary ammonium salt, followed by the decomposition of the resulting ylide (Musker, 1964). For example, Macomber *et al.* (2008) did experiments with D-labeled TMAH to work out the mechanism of TMAH decomposition, using differential scanning calorimetry (DSC), thermal gravimetry (TG), and evolved gas analysis (EGA). They concluded that TMA, methanol, and dimethyl ether were the main resulting products. The extraction of the α -proton to generate a nitrogen ylide is an important degradation mechanism for methyl ammonium species. Deprotonation of the tetramethyl ammonium ion by hydroxide establishes a rapid equilibrium between the tetramethylammonium ion and the nitrogen ylide species and water that combines the deuterium with the proton in the methyl groups. Then, the methoxide formed in this way reacts with $[Me_4N]^+$ via an S_N2 process to generate dimethyl ester.

However, Chempath *et al.* (2008) proposed that the ylide pathway is more reasonable than the S_N2 pathway. These researchers performed Thermogravimetry and mass spectrometry (TG-MS) experiments to evaluate the stability of tetramethylammonium ($[N(CH_3)_4]^+$) under aqueous conditions in the presence of OH^- ions. They verified the H-D exchange, and their results demonstrated that the ylide mechanism plays a crucial role on the decomposition of TMAH. Moreover, they confirmed this pathway by calculation of the energy of the activation barrier, and they proved that it is lower than for the S_N2 pathway. Finally, the ylide pathway can give rise to unstable intermediates with side reaction, including the Stevens rearrangement reactions (Surpateanu *et al.*, 1976), Sommelet–Hauser rearrangement, and Hofmann elimination (Chempath *et al.*, 2010).

The Hofmann elimination is a vulnerable pathway for degradation of n-alkyl-tetramethylammonium (TMA^+) cations (Long and Pivovar, 2012). However, this barrier is also found to depend on the carbon chain length because of steric interference and number of hydrogens susceptible to the Hofmann elimination (Long and Pivovar, 2012). OH^- can attack the α -carbon atom and the cation degrades by the S_N2 pathways. Edson *et al.* (2012) studied the effect of the number of β -hydrogen atoms susceptible to the Hofmann elimination and the mechanism of different alkyltrimethylammonium cations in deuterioxide form using EGA (Fig. 1). The Hofmann elimination is the preferred decomposition pathway for ammonium cations bearing β -hydrogens, and ylide formation reorganizes protons from water into TMA that is formed with a low activation barrier. The stability of cations increased with the blocking of β -hydrogens, and without β -hydrogen, S_N2 reactions occurred, as shown in Fig. 1. However, no studies report the degradation mechanism of TMAH at high temperature.

To distinguish the source of chlorinated organic compounds detected by the SAM instrument (Eigenbrode *et al.*, 2018), Miller *et al.* (2015) evaluated possible carbon sources with and without the Tenax[®] trap, which is used to con-

centrate the evolved species from the martian samples. They found that perchlorates have nearly no effect on the Tenax trap onboard SAM when the trap is not heated above 300°C. In laboratory experiments, there is rare degradation of the trap after hundreds of pyrolysis experiments of Mars analog soils doped with perchlorates (calcium perchlorate, magnesium perchlorate, or iron chloride). Moreover, the effect of calcium perchlorate on the degradation of Tenax and the subsequent by-products have been studied (Buch *et al.*, 2019). The by-products of perchlorates have an impact on the degradation products of Tenax, such as chlorinated phenyl molecules, chlorobenzaldehyde, chlorophthalic acid, and chlorobiphenyl. To date, few studies have reported on the effect of perchlorate on the function of derivatization agents, especially TMAH, at high temperature (600°C). Thus, the influence of perchlorate on the function of TMAH thermochemolysis must be studied to best understand the potential influence of perchlorates on the TMAH experiment on the SAM and MOMA instruments.

This study explores the degradation of TMAH and the effect of calcium perchlorate on TMAH pyrolysis at 600°C (with different heating ramps, including flash pyrolysis and SAM-like ramp pyrolysis at 35°C·min⁻¹) using Pyr-GC-MS with a hydrocarbon trap. From these results, we propose a mechanism for TMAH degradation at a high pyrolysis temperature (600°C) in the presence of calcium perchlorate. These results provide important foundational data for the interpretation of the origin of organic molecules detected by SAM and MOMA.

2. Experimental Design

2.1. Samples and chemical products

A TMAH solution (25% by weight in methanol; Sigma-Aldrich) was used in this study, and calcium perchlorate tetrahydrate (99%; Sigma-Aldrich) was used to make the calcium perchlorate solution. Naphthalene-d8 (isotopic purity, 99 atom % D; Sigma-Aldrich) was used as an internal standard (IS). The concentration of calcium perchlorate solution (0.85 mol·L⁻¹) was measured by atomic absorption spectrometry (Varian Australia Pty Ltd) (Zagatto *et al.*, 1979; Milačič *et al.*, 1992; Fayiga and Ma, 2006; Špirić *et al.*, 2013), using air–acetylene flame test, with a calcium cathode lamp set at the 422.7 nm resonance wavelength.

The abundance of ClO_4^- in TMAH solution (wt %) is given by the following equation:

$$A = \frac{2C_{Ca(ClO_4)_2} \cdot V_{Ca(ClO_4)_2} \cdot M_{ClO_4^-}}{V_{TMAH} \cdot \rho_{TMAH}} \times 100\%$$

where A is the abundance of ClO_4^- in wt %; $C_{Ca(ClO_4)_2}$ is the concentration of $Ca(ClO_4)_2$ solution, 0.85 mol·L⁻¹; $M_{ClO_4^-}$ is the molar mass of ClO_4^- , 99.45 g·mol⁻¹; $V_{Ca(ClO_4)_2}$ is the volume of $Ca(ClO_4)_2$ solution; V_{TMAH} is the volume of TMAH solution, 3 μ L; and ρ_{TMAH} is the density of TMAH solution, 0.866 g·mL⁻¹.

The effect of different wt % of ClO_4^- (0.1, 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, 10.0, 15.0, 20.0, 30.0, 40.0 wt %) on TMAH pyrolysis at 600°C was studied. The calcium perchlorate was dried at room temperature under a dinitrogen flow for 3 h, and the water abundance in the sample was measured by the Karl Fischer method with an Aqua processeur

FIG. 1. Thermal decomposition of alkyltrimethylammonium deuteriooxide, adapted from Edson *et al.* (2012). Case 1: R^1 , R^2 , and $\text{R}^3 = \text{H}$; Case 2: $\text{R}^1 = \text{CH}_3$, R^2 , and $\text{R}^3 = \text{H}$; Case 3: $\text{R}^2 = \text{H}$, R^1 , and $\text{R}^3 = \text{CH}_3$; Case 4: R^1 , R^2 , and $\text{R}^3 = \text{CH}_3$. TS, transition state.

radiometer (Seaman *et al.*, 1949; Burns and Muraca, 1962; Bryan and Bhaskara, 1976; Galletti and Piccaglia, 1988; Ewa and Piotr, 2009). The calibration curve of the moisture detection is shown in Fig. 2. Results show that the content of moisture within the capsule is less than 1.6% and 0.7% when the calcium perchlorate abundance is 40 and 15 wt %, respectively, which ensured that the experimental conditions are more Mars like.

Individual solutions of octanoic acid (C8, $\geq 98\%$; Sigma-Aldrich), nonanoic acid, Kosher (C9, $\geq 96\%$; SAFC), decanoic acid (C10, $\geq 98.0\%$; Sigma Grade), undecanoic acid (C11, $\geq 97.0\%$; Fluka), lauric acid (C12, $\geq 98.0\%$; Sigma-Aldrich), tridecanoic acid (C13, $\geq 98.0\%$; Sigma Grade), myristic acid (C14, 99–100%; Sigma Grade), pentadecanoic acid (C15, $\sim 99\%$; Sigma Grade), palmitic acid (C16, $\geq 99.0\%$; Sigma Grade), heptadecanoic acid (C17, $\geq 98.0\%$; Sigma Grade), stearic acid (C18, $\geq 98.5\%$; Sigma Grade), and arachidic acid (C20, $\geq 99.0\%$; Sigma-Aldrich) were prepared by diluting the pure fatty acids into pyridine ($\geq 99.9\%$; Sigma-Aldrich) solvent. The concentration of each fatty acid is $0.67 \text{ mmol} \cdot \text{L}^{-1}$. For the recovery of fatty

acids with $3 \mu\text{L}$ TMAH, $2 \mu\text{L}$ of the fatty acid solution was used. For the recovery of fatty acids under similar conditions used on Mars by the SAM and MOMA instruments, the original fatty acids solution was diluted to 1000 times, about $2.2 \mu\text{L}$ of diluted fatty acid solution and 0.2 mg of ClO_4^- were used, respectively.

2.2. Pyrolysis experiments

The pyrolysis experiments were performed with an EGA/PY-3030 D micro-oven pyrolyzer (Frontier Lab), installed on the split/splitless (SSL) injector of a Trace GC Ultra gas chromatograph (Thermo Scientific) coupled to a quadrupole mass spectrometer (ISQ LT; Thermo Scientific). Varying volumes of $\text{Ca}(\text{ClO}_4)_2$ solution were injected in a capsule (Eco-Cup; Frontier Lab) under a stream of nitrogen to dry the $\text{Ca}(\text{ClO}_4)_2$ solution, and then, $3 \mu\text{L}$ of TMAH was injected into the capsule. That capsule carried by an eco-stick (Frontier Lab) was attached to the top of the pyrolyzer.

Two kinds of pyrolysis ramps were used in this study. The first one is flash pyrolysis wherein the sample is pushed into a heated and stabilized oven at 600°C for 30 s, after which the sample is removed from the oven. Helium is used as the carrier gas to carry the pyrolysis volatile products into the GC-MS. The second ramp is the SAM-like ramp pyrolysis. During this process, the heart-cut EGA analysis method was used. For that, the sample cup was attached to the pyrolyzer and the pyrolyzer head space was purged for 2 min before proceeding. Then, the sample cup was pushed inside the oven (initial temperature was 50°C), and the oven was heated to the final temperature of 600°C (with a 1 min hold) at the SAM heating rate of $35^\circ\text{C} \cdot \text{min}^{-1}$. The MicroJet Cryo-Trap (Frontier Lab) was used to trap and preconcentrate at -180°C all the released products. When the pyrolysis process was finished, the temperature of the trap was quickly increased to 40°C . Then, all the products were released and sent to the GC-MS through the helium flow.

Finally, to explore the products of TMAH pyrolysis with calcium perchlorate, a stepped pyrolysis of TMAH with and without calcium perchlorate was performed. For this study, the sample was injected into the pyrolyzer and was heated at

FIG. 2. The calibration curve of H_2O detection.

a SAM-like heating rate of $35^{\circ}\text{C}\cdot\text{min}^{-1}$ from 50°C to 100°C , every increase in 100°C up to 1000°C , as $100\text{--}200^{\circ}\text{C}$, $200\text{--}300^{\circ}\text{C}$, $300\text{--}400^{\circ}\text{C}$, $400\text{--}500^{\circ}\text{C}$, $500\text{--}600^{\circ}\text{C}$, $600\text{--}700^{\circ}\text{C}$, $700\text{--}800^{\circ}\text{C}$, $800\text{--}900^{\circ}\text{C}$, and $900\text{--}1000^{\circ}\text{C}$. All experiments were repeated more than three times.

2.3. GC-MS analysis

Analyses were conducted with a Trace GC Ultra gas chromatograph (Thermo Scientific) coupled to a quadrupole mass spectrometer (ISQ LT; Thermo Scientific). The GC is equipped with a Supelco SLB-5MS Inferno column ($30\text{ m}\times 0.25\text{ mm i.d.}\times 0.25\text{ }\mu\text{m}$ film thickness) with 5 m integrated guard column. For the flash pyrolysis, the temperature programming of the column starts at 40°C held for 2 min , then at a heat rate of $3^{\circ}\text{C min}^{-1}$ up to 200°C and then raised to 300°C at a rate of $6^{\circ}\text{C min}^{-1}$ and maintained for 1 min . To mimic the SAM ramp, the temperature programming of the column starts at 40°C hold for 2 min , then at a heat rate of $6^{\circ}\text{C min}^{-1}$ up to 300°C and maintained 1 min . In both ramps, helium was used as the carrier gas and the helium flow rate in the column was $1.2\text{ mL}\cdot\text{min}^{-1}$. The split flow was $24\text{ mL}\cdot\text{min}^{-1}$. The temperature of the SSL injector was set at 280°C . The masses were scanned between m/z 40 and m/z 500. The ionization energy was 70 eV .

The relative abundance of the compounds was obtained through the following equation:

$$C_i = \frac{\frac{A_i}{A_{is}}}{\sum \frac{A_i}{A_{is}}} \times 100\%,$$

where A_i and A_{is} refer to the peak areas of the products and the peak area of the internal standard, respectively.

3. Results

3.1. Flash pyrolysis of TMAH at 600°C

3.1.1. Products of TMAH treated with flash pyrolysis at 600°C . Flash pyrolysis is a high temperature process, in which the sample is rapidly heated at a very high heating and heat transfer rate in the absence of air (Bridgwater and Peacocke, 2000). Samples treated with the flash pyrolysis method almost always yield a greater number and diversity of fatty acid methyl esters than ramped pyrolysis, because the flash pyrolysis step of macromolecules with TMAH thermochemolysis is higher efficient (Williams *et al.*, 2019). Therefore, the flash pyrolysis products of TMAH at 600°C were analyzed. Figure 3 shows the chromatogram of TMAH flash pyrolysis at 600°C , and all products released from flash pyrolysis are listed in Supplementary Table S1. Most of the by-products of TMAH pyrolysis were detected from the retention time (RT) of $1.0\text{--}5.0\text{ min}$; the naphthalene-d8 (internal standard) was eluted at the retention time of 14.80 min . TMA (eluted at $2.06\text{--}2.29\text{ min}$) and dimethyl ether (eluted at 1.95 min) are the main products of TMAH flash pyrolysis degradation at 600°C . The production yield of TMA and dimethyl ether is *ca.* 48% and 25%, respectively, and carbon dioxide formed during the TMAH pyrolysis process accounts for 15% of all pyrolysis products from TMAH pyrolysis. Other nitrogen-bearing compounds account for 12% of all pyrolysis products from TMAH flash pyrolysis, such as N-methyl-ethylamine, N,N-dimethyl-

ethylamine, and the N-O containing compounds such as urea. Various siloxane compounds were detected at different retention times of 6.60, 6.80, 10.69, 11.0, and 13.79 min, which were caused by the column bleeding, a loss of its stationary phase (5% diphenyl/95% dimethyl siloxane).

During the flash pyrolysis of TMAH at 600°C , radicals such as $\cdot\text{H}$, $\cdot\text{CH}_3$, $\cdot\text{CH}_2$, $\cdot\text{CH}_2(\text{CH}_3)_3\text{N}^+$, and $\cdot\text{CH}_2(\text{CH}_3)_2\text{N}^+$ were formed because of the cracking of the bond of nitrogen and a methyl group, the C-H bond in the methyl functional group, and the recombination of these radicals. For example, the hydrogen radicals stabilize the structure of $(\text{CH}_3)_2\text{N}^+\text{CH}_2-$ and TMA was formed (Wang and Liang, 2014). The Hoffman elimination plays a key role in alkene formation, the aromatization of alkenes producing aromatics, such as benzene, and N,N-dimethyl-benzenemethanamine formation from the combination of benzene radicals and $(\text{CH}_3)_2\text{N}^+\text{CH}_2-$. Methanol could be formed through the demethylation of TMAH and the combination of methyl functional group with the OH radicals, and dimethyl ether was formed through the dehydration of methanol. The aldehyde product $(\text{CH}_3)_3\text{N}^+\text{CHO}$ could be generated by the hydrolysis reaction of carbon center radicals, and the aldehyde products could be oxidized by the oxygen radicals from the system and to form the carboxylic acids at high temperature. The possible route of TMAH degradation is shown in Fig. 4.

3.1.2. Effect of $\text{Ca}(\text{ClO}_4)_2$ on flash pyrolysis of TMAH. As described previously, perchlorates have been detected on Mars, with calcium perchlorate thought to be the main source of chlorine (Ming *et al.*, 2014). Therefore, the influence of calcium perchlorate on the pyrolysis behavior of TMAH was investigated; in particular, the pyrolysis behavior of TMAH with calcium perchlorate in different concentrations (0.1, 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, 10.0, and 15.0 wt %) was studied. The resulting chromatograms are shown in Fig. 5. When the perchlorate abundance is lower than 2 wt %, few new products are formed during the flash pyrolysis of TMAH. When the abundance of perchlorate is higher than 2 wt %, new products are detected such as (dimethylamino)acetonitrile (RT: 5.33 min) and dimethyl cyanamide (RT: 5.80 min) with the $\text{C}\equiv\text{N}$ bond, DMF with the aldehyde functional group eluted at 6.26 min, and 1,3,5-trimethyl-1,3,5-triazacyclohexane (TMTAC) with a six-membered heterocyclic aromatic ring eluted at 11.10 min. Pyrrole was formed during the pyrolysis of TMAH, such as 2,5-dimethyl-pyrrole at the retention time of 7.49 min and 4-ethyl-2-methyl-pyrrole at the retention time of 9.83 min. The products of TMAH pyrolysis with calcium perchlorate at a concentration higher than 10 wt % are listed in Supplementary Table S2. There are only three possible Cl-containing compounds at low abundance detected in this study, including 5-chloro-2-pyridinol (RT=10.12, 12.57 min), 5-chloro-1-methylimidazole (RT=10.18, 12.0, and 12.69 min), and 4,5-dichloro-1-methyl-imidazole (RT=15.72 min). The intensity of these peaks is at the detection limit of the instrument.

The distribution of the main products of TMAH flash pyrolysis with 10 wt % calcium perchlorate is shown in Table 1. Most of the products are N-containing compounds. These include TMA, N,N,N',N'-tetramethylmethanediamine, and TMTAC at 12.7%, 21.3%, and 16.7%,

FIG. 3. The chromatogram of TMAH flash pyrolysis at 600°C. respectively. Dimethyl ether and CO₂ are also main products at 11.0% and 13.9%, respectively. The newly formed products of dimethylamino acetonitrile and DMF, of 6.2% and 6.7%, respectively, account for a relatively high proportion compared with other nitrogen-containing by-products.

Figure 6 shows the effects of calcium perchlorate on the main products produced during the flash pyrolysis of TMAH at 600°C. TMA and dimethyl ether are the main compounds

from the flash pyrolysis of TMAH with the presence of calcium perchlorate, as shown in Table 1, and their abundance did not show obvious changes with the increase of calcium perchlorate when its abundance is lower than 5 wt %. TMA abundance increases as calcium perchlorate reaches 2 wt %, and the TMA abundance remains stable as the calcium perchlorate concentration increases to 10 wt %. However, TMA decreases with an increase of calcium

FIG. 4. The mechanism of TMAH degradation via flash pyrolysis.

perchlorate up to 15 wt %, which means that other N-bearing compounds are formed. Dimethyl ether shows a similar trend as TMA.

Nitrogen-containing compounds such as DMF and dimethylamino acetonitrile, and TMTAC and dimethyl cyanamide are formed when calcium perchlorate is higher than 2 wt %, and the yield of DMF and dimethylamino acetonitrile increases with an increase in calcium perchlorate when its abundance is higher than 5 wt %. For example, the amount of DMF formed after the TMAH pyrolysis with the presence of 15 wt % ClO_4^- is *ca.* 2.7 times higher than that from TMAH pyrolysis with calcium perchlorate with the presence of 5 wt % ClO_4^- ; the TMTAC and dimethyl cyanamide show a slight increase with the increase of perchlorate higher than 5 wt %. N,N,N',N'-tetramethyl-methanediamine is one of the most important by-products from TMAH pyrolysis, and the abundance of N,N,N',N'-tetramethyl-methanediamine increases with an increase in calcium perchlorate up to 10 wt %. N,N,N',N'-tetramethyl-methanediamine could possibly be decomposed or transferred to other nitrogen-containing compounds, such as cyanamide or triazine. 1-methoxy-3,3-

diethyltriazene 2-oxide at the retention time of 11.66 min is an intermediate compound, and the abundance of N,N-dimethyl-ethylamine increases slightly with increasing perchlorate concentration. And, N,N-dimethylbenzenamide was detected at a low concentration, indicating that additional perchlorate promotes the formation of these products.

3.2. The pyrolysis of TMAH under SAM experimental conditions

3.2.1. Products of TMAH pyrolysis under SAM experiment conditions. The chromatogram for TMAH pyrolysis using the SAM-like ($35^\circ\text{C}\cdot\text{min}^{-1}$) heating ramp (Fig. 7) is similar to the results of TMAH flash pyrolysis from 50°C to 600°C . Indeed, no compounds of interest were detected after 5 min retention time. TMA and dimethyl ether are the main products of TMAH pyrolysis. Other pyrolysis products of TMAH include nitrogen- and oxygen-containing compounds (Supplementary Table S3). Compared with TMAH flash pyrolysis, there are fewer by-products with TMAH pyrolysis at the SAM-like ramp. This is due to radical

TABLE 1. THE DISTRIBUTION OF THE PYROLYSIS PRODUCTS OF TETRAMETHYLAMMONIUM HYDROXIDE WITH 10 WT % OF PERCHLORATE DURING THE FLASH PYROLYSIS AT 600°C

Compounds	Yields (%)	Compounds	Yields (%)

fragments being formed simultaneously and in a highly reactive state (Onay and Mete Kockar, 2003; He *et al.*, 2014) during TMAH flash pyrolysis at 600°C. Thus, the radicals interact with each other forming more by-products. The pyrolysis products of TMAH pyrolysis at *ca.* 135–140°C have been previously studied (Musker, 1964), with the main products of dimethyl ether and TMA being consistent with our study.

3.2.2. The effect of calcium perchlorate on TMAH under SAM-like pyrolysis experimental conditions. To study the effect of calcium perchlorate on TMAH pyrolysis under SAM-like ramp conditions (35°C·min⁻¹ up to a final temperature of 600°C), the pyrolysis products of TMAH with different calcium perchlorate concentrations were analyzed.

Figure 8 shows the chromatograms of TMAH pyrolysis with Ca(ClO₄)₂ at the SAM-like ramp from 50°C to 600°C. Results show that chloromethane is formed during the pyrolysis of TMAH when calcium perchlorate concentrations are higher than 3 wt %, and chloromethane abundance increases with an increase in calcium perchlorate percentage. This trend may be caused by the decomposition of tetramethylammonium chloride. This reaction (1) can be expressed by the following equation (Lawson and Collie, 1888):

Figure 9 shows the results of calcium perchlorate on TMAH pyrolysis at the SAM-like heating ramp. Dimethyl

SAM, Sample Analysis at Mars.

ether and TMA do not show obvious changes with the increase of calcium perchlorate until the perchlorate percentage is higher than 10 wt %. After 10 wt % perchlorate, the abundance of dimethyl ether and TMA decreases slightly with the increase in perchlorates. At the same time, DMF and TMTAC are formed and become the main pyrolysis products, with a stable trend in their yield with the increase in calcium perchlorate. This demonstrates that the presence of calcium perchlorate can cause the formation of N-containing compounds, and the transfer of N from TMA to other nitrogen-containing compounds was promoted. However, the reaction among these cracking fragments and how these by-products are formed during the TMAH flash pyrolysis and at SAM-like ramp pyrolysis need to be studied.

4. Discussion

4.1. Mechanism of reaction of perchlorate with TMAH during the pyrolysis

To elucidate how calcium perchlorate influences the formation of by-products from TMAH pyrolysis at 600°C , a step pyrolysis experiment was conducted to assess the products of TMAH with calcium perchlorate (at 20 wt %) and without calcium perchlorate. Compared with the SAM-like pyrolysis products of TMAH, there was no obvious difference between the experiments except for the TMAH + 20 wt % $\text{Ca}(\text{ClO}_4)_2$ from the 400°C to 500°C temperature range (Fig. 10). Table 2 summarizes all products of TMAH with and without 20 wt % calcium perchlorate. TMA is the main pyrolysis product and was detected at temperature steps ranging from 100°C to 400°C . This indicates that TMAH can be decomposed at temperatures as low as *ca.* 100°C , and a variety of N-bearing compounds was formed. In the 400 – 700°C range, lower abundances of TMA are detected. At temperatures higher than 800°C , only CO_2 was detected. In the 200 – 500°C range, chloromethane was detected at higher concentrations, indicating that methyl groups are formed during TMAH pyrolysis, as shown in Fig. 11.

Compared with TMAH-only experiment, the numbers of pyrolysis products were increased in TMAH SAM-like ramp pyrolysis in the presence of 20 wt % ClO_4^- . Figure 11 shows the chromatograms of TMAH pyrolysis with the presence of 20 wt % ClO_4^- at different temperatures. Dimethyl ether and TMA are the main products of TMAH pyrolysis. There are also other O- and N-containing compounds that were detected when the pyrolysis temperature was lower than 400°C , such as 1-methoxy-2-(vinylloxy)-ethane and N,N-dimethyl-ethylamine. There was no significant change in the number of by-products when the pyrolysis temperature was lower than 400°C ; however, more than 20 compounds were detected during the TMAH pyrolysis from the 400°C to 500°C temperature range. Approximately 50% of these compounds contain nitrogen. Among these compounds, a high concentration of TMTAC was detected. Other related nitrogen-containing and nitrogen–oxygen-containing compounds were identified, such as dimethyl-cyanamide, dimethylamino-acetonitrile, N-dimethyl-N-D-aspartic acid, pyrrole, and DMF. TMTAC, DMF, and TMA are the main products obtained from the pyrolysis of TMAH with $\text{Ca}(\text{ClO}_4)_2$, and the intensity of TMTAC is the highest, which means that the TMTAC is the most stable form of a nitrogen-containing compound in these experiments.

TMTAC, with a chair conformer with the axial orientation of one CH_3 group based on electron diffraction data (Zverev *et al.*, 2007), is a kind of nucleophilic acyl group transfer reagent and can provide a convenient alternative to the established dialkoxymethyl lithium compounds and lithiodithianes commonly employed as one-carbon nucleophiles, a building block for imidazoles (Subramanian, 2001). It is well known that hexamethylenetetramine (HMT) or hexamine can be formed by the reaction of formaldehyde and ammonia, and they are stable intermediates during the reaction. Ogata and Kawasaki (1964) explained the mechanism and kinetics of the formaldehyde and ammonia reaction, wherein the formation of methylenediamine ($\text{NH}_2\text{CH}_2\text{CH}_2$) is faster than that of hexamine, and a higher ratio of CH_2O versus NH_3 is favorable for the formation of hexamine. They proposed the dimethylamine pathway for

FIG. 8. Chromatograms of TMAH pyrolysis with $\text{Ca}(\text{ClO}_4)_2$ at SAM-like ramp. Peak 1: N,N-dimethyl-ethylamine; peaks 2 and 4: N,N,N',N'-tetramethyl-methanediamine; peak 3: Dimethylamino-acetonitrile; peak 5: DMF; peak 6: N-ethyl-acetamide; peak 7: TMTAC.

the formation of HMT during the reaction of formaldehyde and ammonia, which has been confirmed by Zeffiro *et al.* (2016). Their results showed that dimethylamine plays a key role in the formation of HMT, which are stable intermediates. Through a dehydration process, methylenediamine reacts with dimethylamine and forms the cyclotrimethylene-triamine, which is the related heterocyclic compound of $(\text{CH}_2\text{NR})_3$, where R is hydrogen; however, if R represents a methyl group, the product should be TMTAC.

This reaction led to the conclusion that the presence of aldehyde and amine functional group-containing compounds is key factor for the formation of TMTAC. Results

from our study indicate that DMF, with both aldehyde and amine functional groups, could be the main compound formed simultaneously with the formation of TMTAC. Thus, we speculate that DMF is a vital intermediate and plays a key role in the formation of TMTAC. DMF is a polar solvent used widely in industrial processes that can dissolve a wide range of both organic and inorganic compounds because of its large dipole moment, a high dielectric constant, and its donor-acceptor properties (Attri *et al.*, 2010). It can also be used as a dehydrating agent and catalyst in the dehydration of aldoximes to nitriles (Supana *et al.*, 2007). The oxygen atom in DMF is the negative pole and is an

FIG. 9. The effect of $\text{Ca}(\text{ClO}_4)_2$ on the pyrolysis products of TMAH at a heating rate of $35^\circ\text{C}\cdot\text{min}^{-1}$ from 50°C to 600°C .

ideal hydrogen bond acceptor that extends out from the rest of the molecule. The TMTAC cannot be the condensation product of nitriles because the lack of methyl groups on the nitrile N atom makes it impossible to form TMTAC.

To confirm the function of DMF during the formation of TMTAC, the flash pyrolysis products of DMF at 600°C were studied. Figure 12 shows the chromatogram of DMF flash pyrolysis at 600°C , and the main pyrolysis products are listed in Supplementary Table S4. Results show that the TMTAC was formed during the pyrolysis of DMF at 600°C , and N,N,N',N' -tetramethyl-methanediamine (RT = 2.77 and 3.02 min), dimethylamino-acetonitrile (RT = 4.02 min), and some olefins such as 1-nonene (RT = 8.53 min) and 1-decene (12.78 min) were detected. These results indicate that DMF is the main intermediate for the formation of these compounds.

The question remains of how DMF is formed during the TMAH pyrolysis at 600°C in the presence of calcium perchlorate. The thermal decomposition process of calcium perchlorate is an integral step in understanding this process. Migdał-Mikuli and Hetmańczyk (2008) studied the thermal decomposition of calcium perchlorate, which includes three main stages: the first stage is the process of dehydration as shown in reaction (2), between 184°C and 287°C ; the phase transition of solid to melted calcium perchlorate is the second stage according to DSC curve at 346 – 416°C as shown in reaction (3); the third stage is the decomposition of $\text{Ca}(\text{ClO}_4)_2$ concurrent with the formation of CaCl_2 and the release of O_2 at about 462°C [reaction (4)]. When water is

FIG. 10. The chromatography of TMAH with 20 wt % ClO_4^- , TMAH, and $\text{Ca}(\text{ClO}_4)_2$ pyrolysis at 400 – 500°C at a heating rate of $35^\circ\text{C}\cdot\text{min}^{-1}$.

present, CaCl_2 could react with H_2O and release HCl at the pyrolysis temperatures higher than 450°C (Glavin *et al.*, 2013). The oxidation of TMAH was caused by the oxygen released during the thermal decomposition of calcium perchlorate from 400°C to 500°C , which can provide enough energy needed for the thermal decomposition of calcium perchlorate, as shown in Figs. 10 and 11.

During the pyrolysis of TMAH, TMA was detected, which is the most likely precursor of DMF, which means that the methyl functional group of TMA or tetramethylammonium ion could be oxidized by O_2 released from the degradation of calcium perchlorate. The reaction between CH_3 and O_2 may proceed through three different channels, as shown in reactions (5), (6), and (7) (Yu *et al.*, 1995).

FIG. 11. Chromatograms of TMAH pyrolysis (a heating rate of $35^{\circ}\text{C}\cdot\text{min}^{-1}$) with 20 wt% calcium perchlorate at different temperatures. Peak 1: CO_2 ; peak 2: Chloromethane; peak 3: TMA and isomers; peak 4: N,N-dimethyl-ethylamine; peaks 5 and 6: N,N,N',N'-tetramethyl-methanediamine and isomers; peak 7: 1-Methyl-pyrrole; peak 8: Dimethylamino-acetonitrile; peak 9: Dimethyl-cyanamide; peak 10: N,N-dimethylformamide; peak 11: TMTAC; peak 12: Dimethyl ether.

Reaction (5) is the main channel at low temperatures about 300 K. Reactions (6) and (7) play a major role in the consumption of CH_3 during methane oxidation at elevated temperatures. For the oxidation of TMA in this study, results showed that channel (7) is the main process of TMAH oxidation because the hydrogens are active and can be transited among different methyl groups (Vieira *et al.*, 1984; Filley *et al.*, 1999). Therefore, the oxidation of the methyl functional groups of the TMA or TMAH ion by oxygen released during the decomposition of calcium perchlorate is the main source of DMF formation. However, oxygen has consistently been present such that the formation of the

FIG. 12. The chromatography of DMF flash pyrolysis at 600°C . DMF, N,N-dimethylformamide.

intermediate $(\text{CH}_3)_2\text{NCH}_2\text{O}_2$ was not rate determining (Onel *et al.*, 2013). Therefore, the formation of DMF with different percentages of calcium perchlorate did not substantially change with the $35^{\circ}\text{C}\cdot\text{min}^{-1}$ heating rate.

However, the potential energy surface of OH formation is pressure dependent (Onel *et al.*, 2013). The pressure of TMAH flash pyrolysis increases immediately when the sample is injected into the pyrolysis chamber. At the same time, many radical fragments are formed and volatile volumes increase to facilitate the combination among these radicals and form different chemical products. Therefore, the yield of DMF during the flash pyrolysis increased with the increasing amount of calcium perchlorate, and there are many more by-products of TMAH with the SAM-like ramp pyrolysis. For the same reason, the formation of TMTAC showed a relatively stable trend with SAM-like ramp pyrolysis. Additionally, TMTAC increased with an increase of calcium perchlorate, which could also be facilitated by the higher formation and mass transfer rate of hydrogen radicals during the flash pyrolysis.

The cyanamide and acetonitrile feature a nitrogen atom (sp^3 or sp^2) bearing a nitrile group and possess unique properties as building blocks for organic synthesis owing to their original unique structures (Larraufie *et al.*, 2012). Cyanamide- and acetonitrile-bearing compounds are formed during TMAH pyrolysis at 600°C with the presence of calcium perchlorate. Examples of these products include dimethylamino-acetonitrile (RT=5.26 min, Fig. 5) and dimethyl-cyanamide (RT=5.80 min, Fig. 5), which indicates not only oxidation but also cyanations occur during the TMAH pyrolysis with calcium perchlorate. The simplest form of cyanamide can be formed naturally.

Cyanamide is also considered as an important molecule in prebiotic chemistry with the condensation of cyanamide with α -hydroxy aldehydes being a possible prebiotic route to cytosine-type nucleosides (Anastasi *et al.*, 2006). Cyanamide can be formed through several different methods, including the alkylation and acylation of cyanamides, the cyanation of amines and their derivatives, and dehydration of urea and amide oximes (Nekrasov, 2004). Doubly labeled nitrile compounds have been synthesized by combining the source of $-\text{CN}$ from DMF (96% ^{13}C source) and ammonia

FIG. 13. The plausible mechanism of TMAH degradation with the presence of calcium perchlorate at 600°C.

(98% ^{15}N source) in the palladium-catalyzed cyanation of aryl C-H bonds (Kim and Chang, 2010). Cyanamide can also be formed by the direct transformation of DMF (Ding and Jiao, 2011). The elements N and C in the cyano functional group derive from DMF ($\text{C}_3\text{H}_7\text{NO}$), whereas O_2 and $-\text{CH}_3$ are the sources of the elements O and C in the generated $-\text{CHO}$ group; in other words, the functional group $-\text{CHO}$ is generated from methyl oxidation by O_2 . Results showed that the presence of H_2O decreases the yield of $-\text{CN}$ formation, which could be caused by the $-\text{CN}$ group hydration to amine (Camino *et al.*, 1983).

The formation of various intermediates could also be formed through the Ritter reaction (Guérinot *et al.*, 2012; Yin *et al.*, 2019). Therefore, hydration processes could occur during TMAH degradation. As shown in Fig. 10, some urea-related products are formed, such as urea and N,N-dimethyl urea. Therefore, DMF is the key intermediate for the formation of cyanamide and (dimethylamino)acetonitrile during the TMAH pyrolysis in the presence of calcium perchlorate higher than 10 wt %. This is demonstrated by the pyrolysis of DMF at 600°C . Therefore, the formation of cyanamide and nitriles, CO_2 , and other by-products related to DMF formation is influenced by the formation rate of DMF; hence, these compounds' formation remains stable. The reaction route can be seen in Fig. 13.

There are two competitive processes involved: the oxidation by O_2 and hydrogenation reduction by hydrogen radicals including $\cdot\text{H}$ radicals and $\cdot\text{CH}_3$ radicals formed from the demethylation reactions of TMAH. The nitrogen ylide could be oxidized to acyl-containing compounds and then further oxidized to carboxyl by O_2 , followed by the methylation process, or by the formation of CO_2 through carboxyl elimination; and the intermediate products could be stabilized by hydrogen radicals. CO_2 could also result from the partial hydrolysis of secondary and tertiary amide groups formed in branching and cross-linking reactions (Camino *et al.*, 1983). Alternatively, the methyl groups could form the alkyl chain products via the free radical polymerization mechanism (Matheson *et al.*, 1951).

At the same time, the aromatization of these active free radicals could occur according to the aromatization mechanism (He *et al.*, 2019b). The cyclization reaction also plays a key role during the degradation of TMAH at 600°C , such as the formation of pyrrole compounds that may be formed through the reaction of amine functional groups with α -hydrogen (Choi and Ko, 2011). However, no researchers have reported the direct formation of $-\text{CN}$ from TMAH pyrolysis, which would represent a new pathway for cyanamide and nitrile formation. However, the hydroxyl ion can catalyze the hydrolysis of cyanamide, which could be decomposed in alkaline solutions to urea (Hetherington and Braham, 1923) as well as polymerized to dicyanodiamide.

As mentioned before, the decomposition of TMAH at low temperatures (*ca.* 200°C) has two possible pathways: the $\text{S}_{\text{N}}2$ and the ylide pathway. Based on the TMAH pyrolysis products at 600°C , the nucleophilic attack of TMAH and the ylide intermediate pathway is a more satisfactory explanation. Ylide is another important compound for the formation of nitrogen-containing by-products, including dimethyl-methanolamine, dimethylamine, and N,N,N',N'-tetramethyl-methanediamine (Camino *et al.*, 1983), all formed during the TMAH pyrolysis process. For example, unstable ylides can decompose to produce dimethyl ethylamine and polyethylene, and the ylide would be involved in the formation of the dimethyl ether (Wittig and Polster, 1956). The ylide can rearrange via intramolecular hydrogen exchange to form the dimethyl ether products mixed with CH_3OCH_3 , $\text{CH}_2\text{-DOCH}_3$, CHD_2OCH_3 , and CD_3OCH_3 (Muskier and Stevens, 1968; Kenig *et al.*, 2016). The charge distribution of N-containing ylides is largely affected by the electron-withdrawing properties of the quaternary nitrogen (Tsuchiya and Seno, 1979). Other than the Mannich reaction (Arend *et al.*, 1998; Marques, 2006), *in situ* dehydration of water from the hemiaminal products of the reaction between formaldehyde-containing compounds and an amine also plays an important role in the formation of different alkyl ylides, as shown in Fig. 13.

FIG. 14. The effect of calcium perchlorate on the recovery of fatty acids by TMAH thermochemolysis.

FIG. 15. The recovery of fatty acids with TMAH thermochemolysis on Mars-like conditions. The concentration of perchlorate is the ratio of perchlorate to organics (300 ppb of fatty acids).

4.2. Fatty acid recovery with TMAH thermochemolysis in the presence of calcium perchlorate

Finally, the performance of TMAH on the recovery of fatty acids (16 nmol) was studied. Although there are several new products formed during the pyrolysis of TMAH with higher than 10 wt % calcium perchlorate, the highest concentration of ClO_4^- detected on Mars is ~ 1 wt % (Archer *et al.*, 2016; Sutter *et al.*, 2017b). Therefore, the effect of calcium perchlorate (lower than 5 wt %) on the detection of fatty acids was studied. Naphthalene-d8 was used as the internal standard, and the fatty acids were quantified by rationing the peak area of the fatty acid divided by the peak area of naphthalene-d8. Figure 14 shows the recovery of fatty acids without and with different percentages of calcium perchlorate. Results demonstrate that the increase in calcium perchlorate up to 5 wt % has nearly no effect on the detection of fatty acids. Additionally, the concentration of the methyl group (about 86 μmol , calculation is shown in the Supplementary Data) used to derivatize the fatty acids is much greater than (in excess) the concentration needed to complete fatty acid methylation (of 16 nmol, calculation is shown in the Supplementary Data). Therefore, the calcium perchlorate has no obvious effect on the recovery of the fatty acids.

To further explore how calcium perchlorate may affect the detection of organics on Mars, experiments were conducted that utilized the same concentration of fatty acids and perchlorate as has been reported from Mars (Guzman *et al.*, 2018). Chlorobenzene has been detected on Mars at 300 ppb and is used as a proxy for the concentration of organics on Mars for this experiment. Perchlorate on Mars has been detected at about 1% (Ming *et al.*, 2014). The *Curiosity* rover that carries the SAM instrument is capable of delivering *ca.* 20 mg of sample to SAM for a TMAH thermochemolysis experiment. Therefore, *ca.* 6×10^{-9} g (300 ppb $\times$ 20 mg = 6×10^{-9} g) of fatty acids and 0.2 mg (1% $\times$ 20 mg) ClO_4^- were set to simulate the Mars conditions for this experiment.

Figure 15 shows the recovery of fatty acids with and without calcium perchlorate on Mars-like conditions. Different percentages of calcium perchlorate have nearly no effect on the detection of fatty acids at these ratios. The calcium perchlorate used in this study can release 4×10^{-6} mol of O_2 , the abundance of TMAH is about 4.4 times higher than the amount of O_2 , and the C abundance is 17.6 times higher than that of O_2 (calculation is shown in the Supplementary Data). However, TMAH can be degraded to methyl radicals, which more readily react with O_2 . The fatty acids used in these experiments are very stable (Rustan and Drevon, 2001) and have been derivatized to methyl esters by TMAH thermochemolysis, the methylation of the groups containing esters and ethers could increase the thermodynamic stability and chromatographic detection by GC-MS (Tadini *et al.*, 2015). However, methyl groups can be formed when TMAH pyrolysis temperatures reach to 100°C, readily driving forward reactions with O radicals (Lee and Bozzelli, 2003). The presence of calcium perchlorate did not show obvious effects on fatty acid recovery (about 11.8 pmol, calculation is shown in the Supplementary Data). Hence, the excess TMAH to sample ratio is essential for the detection of organics with the SAM and MOMA instruments. However, long-alkyl chains in fatty acids tend to make their detection more difficult.

5. Conclusions

In this study, the degradation of TMAH with and without the presence of calcium perchlorate at flash pyrolysis and SAM-like ramp pyrolysis to 600°C was studied. Some chloride-related compounds were detected during TMAH pyrolysis with higher than 10 wt % calcium perchlorate, including chloromethane, tetramethylammonium chloride, 5-chloro-2-pyridinol, 5-chloro-1-methylimidazole, and 4,5-dichloro-1-methyl-imidazole. Although the peak intensity of these chlorinated compounds was more than 1000 times lower than that of the main products, they are the potential

candidates for the chloride-containing by-products of TMAH. Therefore, TMAH showed little reactivity with chlorine-containing substances.

We also conclude that calcium perchlorate does not affect TMAH degradation at an SAM-like ramp pyrolysis temperature of 600°C when calcium perchlorate concentrations are lower than 10 wt %. Although TMA and dimethyl ether are the main by-products of TMAH pyrolysis, some new by-products are formed when the calcium perchlorate concentrations are higher than 10 wt %. DMF is formed because of methyl group oxidation by O₂ released from the decomposition of calcium perchlorate and followed by the formation of cyanamide and acetonitrile through the cyanation route of amines. TMTAC is formed by the trimerization of DMF, which is a crucial intermediate for the formation of other nitrogen-containing by-products of TMAH. Urea is formed through the Ritter reaction and the Mannich reaction, and the Steven rearrangement and the Hofmann elimination are involved in the formation of various intermediates and ylides. However, in our experimental conditions, calcium perchlorate did not affect the recovery of fatty acids with TMAH thermochemolysis, even when the fatty acid volume was low. These lines of evidence demonstrate that TMAH is a good thermochemolysis reagent at high temperature (600°C) for the methylation and detection of organics on Mars with the SAM and MOMA instruments.
